(REceived 11 February 1998; revised manuscript received 24 June 1998)

Photoexcited quasiparticle relaxation dynamics are investigated in a YBa$_2$Cu$_3$O$_{7-\delta}$ superconductor as a function of doping $\delta$ and temperature $T$ using ultrafast time-resolved optical spectroscopy. A model calculation is presented that describes the temperature dependence of the photoinduced quasiparticle population $n_{pe}$, photoinduced transmission $\Delta T/T$, and relaxation time $\tau$ for three different superconducting gaps: (i) a temperature-dependent collective gap such that $\Delta(T)\rightarrow0$ as $T\rightarrow T_c$, (ii) a temperature-independent gap, which might arise for the case of a superconductor with preformed pairs, and (iii) an anisotropic (e.g., $d$-wave) gap with nodes. Comparison of the theory with data of photoinduced transmission $|\Delta T/T|$, reflection $|\Delta R/R|$, and quasiparticle recombination time $\tau$ in YBa$_2$Cu$_3$O$_{7-\delta}$ over a very wide range of doping ($0.1<\delta<0.48$) is found to give good quantitative agreement with a temperature-dependent BCS-like isotropic gap near optimum doping ($\delta<0.1$) and a temperature-independent isotropic gap in underdoped YBa$_2$Cu$_3$O$_{7-\delta}$ ($0.15<\delta<0.48$).

A pure $d$-wave gap was found to be inconsistent with the data. [S0163-1829(99)(09301-7)]

I. INTRODUCTION

Ultrafast optical time-resolved experiments performed on high-$T_c$ superconductors in recent years have shown that a substantial transient change of the optical transmission or reflection can be induced in these materials by ultrashort laser-pulse photoexcitation (PE). What makes these studies particularly interesting is the fact that in optimally doped superconductors where $T_c$ is a maximum, the amplitude of the observed photoinduced transmission signal $|\Delta T/T|$ (or reflection $|\Delta R/R|$) appears to increase dramatically below $T_c$. Furthermore, recently it was found that in underdoped YBa$_2$Cu$_3$O$_{7-\delta}$ ($\delta>0.15$), the increase in amplitude could not be correlated with $T_c$, but rather with the so-called "pseudogap" temperature $T^*$ which increases with increasing $\delta$. These observations together suggest rather strongly that the photoinduced effects are related to the opening of a gap (or pseudogap) in the density of states close to the Fermi energy. For optimally doped cuprate superconductors—on which most experiments were done so far—there has been substantial agreement in the literature regarding the experimental data. However, various groups have proposed very different explanations for the observed effects$^{1,3,4,6}$ and their origin has remained controversial.$^7$

In this paper we present a calculation of the photoinduced optical response in a superconductor for weak excitation and compare our results with systematic experimental data on YBa$_2$Cu$_3$O$_{7-\delta}$ as a function of $\delta$ and $T$. We derive expressions for the temperature dependence of the photoexcited quasiparticle density $n_{pe}$ and photoinduced transmission amplitude $|\Delta T/T|$ for different possible gaps (or pseudogaps) that might be applicable to high-$T_c$ cuprates. The simplest case considered is that of a gap, whose temperature dependence is mean-field-like and is approximated using a BCS function. The second case considered is for a temperature-independent "pseudogap" that is relevant for a superconductor where condensation of preformed pairs into a superconducting state occurs at $T_c$ but pairing takes place above this temperature. In this case the gap is not due to a collective effect, but essentially represents the pair-binding energy $E_B$ and is—to first approximation—temperature independent. Finally we discuss the case of an anisotropic gap with nodes, such as one might expect for a $d$-wave superconductor. In Sec. V we present a calculation of the temperature dependence of the quasiparticle relaxation rate $\tau$. Comparisons of the theoretical predictions with experimental data are made in each case and a detailed discussion is given in Sec. VI.

II. EXPERIMENTAL DETAILS

The time-resolved experiments were performed using 100-fs, 800-nm pulses from a Ti:sapphire laser using single high-frequency modulation of the pump at 200 kHz. The YBa$_2$Cu$_3$O$_{7-\delta}$ thin-film samples were grown on MgO or SrTiO$_3$ substrates and annealed in oxygen to obtain different O concentrations $\delta$. The $T_c$ was measured by measuring the ac susceptibility in each case. The transition widths, defined as the temperature where $\chi$ drops to 90% of full diamagnetism, were typically 1–2 K for $\delta<0.15$ and 4–7 K for $\delta>0.15$. The oxygen concentration was determined from $T_c$, which brings in some uncertainty near optimum doping, since the optimum $T_c$ for YBa$_2$Cu$_3$O$_{7-\delta}$ (YBCO) is 90 K on SrTiO$_3$ substrates and 89 K on MgO substrates, which is 2–3 K lower than in single crystals. The typical film thicknesses were 100–120 nm and all experiments were performed in transmission through the sample. The typical energy of the laser pulse is 0.2 nJ, and the laser spot size typically 100 $\mu$m in diameter. In estimating the photoexcited carrier density, the absorption length was assumed to be $l=0.1$ $\mu$m. The cw temperature rise of the superconductor film due to laser heating was calibrated using a 30-$\mu$m YBCO superconducting microbridge from the same batch and on the same substrate as in the optical experiments by measuring the change in resistivity with a four-probe contact method. This tempera-
tation offset was then taken into account in the plots shown in Figs. 1–6. The error in the sample temperature is thus reduced to less than ±2 K.

The photoinduced transmission \( \Delta \Pi / T \) through two different films with \( T_c = 90 \) and 53 K, respectively, is shown in Fig. 1 at different temperatures above and below \( T_c \). There are two decay components in each case, a fast component with \( \tau \sim 0.3-2 \) ps, and a longer-lived component with \( \tau_e > 10 \) ns, which appears as a nearly flat background already discussed elsewhere. The latter will not be analyzed here, except that it will be taken into account in the fitting procedure. The time evolution of the traces was fitted (shown by the solid lines in Fig. 1) using a model with a single exponential decay and a Gaussian temporal profile pump pulse, from which the amplitude of the photoinduced transmission \( |\Delta \Pi / T| \) and relaxation time of the fast component \( \tau \) was determined. The temperature dependence of \( |\Delta \Pi / T| \) and \( \tau \) derived from the fits are plotted in Figs. 2, 4, and 5 and will be discussed together with the theory in the following sections.

### III. Initial Photoexcited Carrier Relaxation

The initial phase of PE carrier relaxation after absorption of a pump laser photon proceeds very rapidly. After the laser pulse excites an electron-hole pair, these PE carriers thermalize among themselves with a characteristic time of \( t_e \sim \hbar E_F/2 \pi E^2 \), where \( E \) is the carrier energy measured from the Fermi energy \( E_F \). In this thermalization process, quasiparticle avalanche multiplication due to electron-electron collisions takes place as long as \( \tau_e < \tau_e^{-1} \) is less than the electron-phonon (e-ph) relaxation time \( \tau_{e,ph} \). Electron-phonon relaxation becomes important when the quasiparticle (QP) energy is reduced to \( E = \sqrt{\hbar E_F^2/2 \pi \tau_{e,ph}} \approx 30-50 \) meV (assuming \( E_F = 0.1-0.2 \) eV). \( \tau_{e,ph} \) has been determined experimentally for the case of a YBa\(_2\)Cu\(_3\)O\(_{7-\delta}\) (Ref. 8) as well as Bi\(_2\)Sr\(_2\)CaCu\(_2\)O\(_{8+x}\) and Bi\(_2\)Sr\(_2\)Ca\(_2\)Cu\(_3\)O\(_{10+x}\) (Ref. 9) from relaxation-time fits in time-resolved experiments using intense laser pulses. Using the formula of Allen, the e-ph relaxation time for YBCO has been found to be \( \tau_{e,ph} = T / 3 \lambda (\omega^2) = 100 \) fs for initial carrier temperatures \( T_c = E_I / C_e \) in the range 3000 K (Ref. 8) and \( \tau_{e,ph} \approx 60 \) fs for \( T_c = 410 \) K. Here \( E_I \) is the energy density per unit volume deposited by the laser pulse, \( C_e \) is the electronic specific heat, \( \lambda \) is a constant that characterizes the electron-phonon interaction, and \( (\omega^2) \) is a mean-square phonon frequency. \( \lambda \) has been determined from these experiments to be in the range \( 0.9 < \lambda < 1 \) both in YBa\(_2\)Cu\(_3\)O\(_7-\delta\) and Bi\(_2\)Sr\(_2\)CaCu\(_2\)O\(_8+x\) superconductors. In experiments that we are considering here, the laser intensities are significantly smaller, and the photoexcited electronic temperature \( T_e \) is only few K in excess of the lattice temperature, i.e., \( T_e \approx T_c \), which gives an e-ph relaxation time \( \tau_{e,ph} \approx 10 \) fs. Under these near-equilibrium conditions where the carrier temperature is near the lattice temperature, this value of \( \tau_{e,ph} \) can be compared to the relaxation time determined from infrared reflectivity measurements. For energies of the order of 30–50 meV, \( h \tau \sim 3000 \) cm\(^{-1} \) (\( \tau \sim 16 \) fs) (Ref. 11) in good agreement with the estimated \( \tau_{e,ph} \approx 10 \) fs. In the absence of a gap in the low-energy density of states, this is the time scale of the electron-phonon thermalization.

In the presence of the gap the situation is strongly modified and a bottleneck in the relaxation occurs after \( \tau \approx 10 \) fs. As a result QP’s accumulate near the gap, forming a nonequilibrium distribution. Each photon thus creates 30–40 QP’s given by \( E_{Q P} = 2 \Delta \), where \( E_{pump} = 1.5 \) eV is the laser pump photon energy and \( 2 \Delta \) is the energy gap. Because the final relaxation step across the gap is strongly suppressed, the QP’s together with high-frequency phonons (with \( \hbar \omega > 2 \Delta \)) form a near-steady-state distribution. The QP recombination dynamics of this system is governed by the emission and reabsorption of high-frequency phonons. Phonons with \( \hbar \omega < 2 \Delta \) do not participate in the direct relaxation of the QP’s, since in this case the QP final states would lie in the gap. (A quantitative justification for the assumption that phonons play a dominant role in the QP relaxation will be given in Sec. V.) The basis for these pump-probe experiments is that this near-equilibrium QP population can be very effectively probed using excited-state absorption using a suitable second optical probe pulse, giving direct information on QP dynamics and the nature of the gap itself.

Since the probe laser photon energy \( E_{probe} \) is typically well above the plasma frequency in high-\( T_c \) superconductors, we make the approximation that the transition probability for the probe light is given by Fermi’s ‘golden rule,’ with photoinduced quasiparticles as initial states and with final unoccupied states well above the Fermi energy in a band that lies approximately at \( E_0 \approx E_{probe} \). The amplitude of the photoinduced absorption (PA) \( \Delta A / \Delta R \) is then proportional to the photoinduced transmission \( |\Delta \Pi / T| \) (and in the linear approximation also to \( |\Delta R / R| \)) which is in turn proportional to the number of photoexcited quasiparticles \( n_{pe} \). The probe signal is thus weighted by the O-Cu charge-transfer dipole matrix element and the joint density of states (JDOS), so \( |\Delta \Pi / T| \approx n_{pe} |\rho_f M_{ij}|^2 \), where \( n_{pe} \) is the photoexcited carrier density, \( \rho_f \) is the final density of unoccupied states, and

![Figure 1](image-url)
is phonon frequency cut off, and \( \nu \) is the effective number of phonon modes per unit cell participating in the relaxation. Taking into account that \( n_{pe} = (n_{T^*} - n_T) \ll n_T \) and assuming that \( n_T = 2N(0)/k_B T \exp(-\Delta/k_B T) \), the number of photo-generated quasiparticles at temperature \( T \) is given by

\[
n_{pe} = \frac{\mathcal{E}_i/\Delta}{1 + \frac{2\nu}{N(0)\hbar \Omega_c}\exp[-\Delta/k_B T]}.
\]

For the case of a temperature-dependent gap \( \Delta(T) \), Eq. (3) will be slightly modified:

\[
\left( (n_{T^*} - n_T) + \frac{\nu}{\hbar \Omega_c N(0)^2 \pi \Delta(T)} (n_T^2 - n_T^2) \right) \times (\Delta(T) + k_B T/2) = \mathcal{E}_i.
\]

We approximate \( n_T = 2N(0)\sqrt{\pi \Delta(T)}k_B T^2 \exp(-\Delta(T)/T) \) (Ref. 13) with \( k_BT/\Delta \), resulting in a slightly modified expression for \( n_{pe} \):

\[
n_{pe} = \frac{\mathcal{E}_i(\Delta(T) + k_B T/2)}{1 + \frac{2\nu}{N(0)\hbar \Omega_c} \sqrt{\frac{2k_B T}{\pi \Delta(T)}} \exp[-\Delta(T)/k_B T]}.
\]

We note that in Eqs. (4) and (6), the explicit form of \( n_{pe} \) (and hence also \( |\Delta|/|A| \) or \(|\Delta/T^*|\)) depends only on the ratio \( k_BT/\Delta \), showing that the intensity of the photoresponse is a universal function of \( k_BT/\Delta \) as long as the particular functional form of the temperature dependence \( \Delta(T) \) is the same. Another important feature of expressions (4) and (6) is that at \( T = 0 \), \( n_{pe} \propto 1/\Delta(0) \), which allows a determination of \( \Delta(0) \), as long as the experimental parameters required to calculate \( \mathcal{E}_i \) are recorded sufficiently precisely.

Since the decay of each phonon involves the creation of two quasiparticles, the number of high-frequency phonons is proportional to the square of the number of quasiparticles \( n_T \), at temperature \( T^* \). (Taking into account conservation of energy \( \nu \) at higher pulse energies when \( n_{pe} \) becomes large, we expect a crossover of the photoresponse from a linear dependence on laser power \( n_{pe} \propto I \) to a square-root dependence \( n_{pe} \propto \sqrt{I} \) at very high intensities.)

To enable comparison of the temperature dependences of the photoinduced transmission given by Eqs. (4) and (6) with experiments, we have plotted them as a function of temperature in Figs. 2(b) and 2(c), respectively. The values for the constants for \( YBa_2Cu_3O_7-\delta \) are \( \nu = 10-20 \), \( N(0) = 2.5-5 \text{ eV}^{-1} \text{ spin}^{-1} \text{ cell}^{-1} \), \( \Omega_c = 0.1 \text{ eV} \). At low temperatures \( n_{pe} \) is essentially \( T \) independent in both cases, falling off at higher temperatures. However, the above-the figure it is clear that the high-temperature behavior is quite different in the two cases. In the case of the \( T \)-dependent gap [Fig. 2(c)], the decrease in \( |\Delta/T^*| \) is much more pronounced and starts quite close to \( T_c \) at \( T/T_c \approx 0.8 \) dropping to zero at \( T_c \). In the temperature-independent gap case [Fig. 2(b)], the photoinduced transmission starts to drop at much lower temperatures near \( T/T^* \approx 0.4 \), dropping exponentially at high temperatures. Also, a notable prediction of Eq. (6) for the \( T \)-dependent gap is a small peak near \( T/T_c \approx 0.7 \), which is not present in the case of a temperature-independent gap formula (4).
FIG. 2. (a) The photoinduced transmission amplitude $|\Delta T/T|$ in YBa$_2$Cu$_3$O$_{7-x}$ as a function of temperature for three different $\delta$: for $\delta=0.48$ (open squares), $\delta=0.18$ (solid triangles) and $\delta=0.1$ (open circles). (b) The solid line is a plot of the photoinduced transmission amplitude as a function of temperature for a temperature-independent gap using expression (4) as a function of $T/T^*$. The data points are for underdoped samples with $\delta=0.18$ with $T_c=77$ K (solid triangles), $\delta=0.32$ with $T_c=62$ K (open triangles), $\delta=0.44$ with $T_c=53$ K (solid circles), and $\delta=0.48$ with $T_c=48$ K (open squares), respectively. (c) The solid line is the calculated photoinduced transmission amplitude from Eq. (6) for a temperature-dependent gap as a function of normalized temperature $T/T_c$ and data for the near optimally doped samples $\delta=0.1$ ($T_c=90$ K) from Mihailovic et al. (Ref. 5) (open circles), Stevens et al. (Ref. 4) (open squares), and Han et al. (Ref. 1) (solid triangles). Note: the original data points of Ref. 1 were shifted by 7 K in temperature. The solid lines in (a) are fits with Eq. (4) for $\delta=0.48$ and $\delta=0.18$ and Eq. (6) for $\delta=0.1$.

In Fig. 2(a) we have plotted the data for the photoinduced transmission amplitude for YBa$_2$Cu$_3$O$_{7-x}$ as a function of temperature for three different $\delta$. Both the magnitude and the temperature dependence are seen to be strongly doping dependent. For comparison with theory, superimposed on the theoretical curves in Figs. 2(b) and 2(c) we have plotted the normalized photoinduced reflectivity and transmission data for YBa$_2$Cu$_3$O$_{7-x}$ with different $\delta$. The data for a number of underdoped samples$^5$ in the range $0.15<\delta<0.48$ have been scaled onto a common temperature scale as suggested by formula (4) and plotted as a function of $T/T^*$ in Fig. 2(b). $T^*$ is defined as the point where the amplitude of signal $|\Delta T/T|$ drops to some fixed value (for example to 5% of the maximum value). The data can be seen to fit the theoretical curve remarkably well.

For near optimally doped YBa$_2$Cu$_3$O$_{7-x}$ ($\delta<0.1$) the data are scaled by $T_c$ and are plotted as a function of reduced temperature $T/T_c$. However, this time the data are superimposed on the prediction for the $T$-dependent BCS-like gap [Eq. (6)] in Fig. 2(c). In this case also, the fit is seen to be good, including the small maximum at $T/T_c=0.7$. This maximum is particularly well observed in the data by Han et al.$^1$ and by Mihailovic et al.$^5$ although it is not evident in the data of Stevens et al.$^4$

The experimental data thus appear to scale onto one of the two theoretical curves, the near optimally doped YBa$_2$Cu$_3$O$_{7-x}$ data ($\delta<0.1$) agreeing very well with Eq. (6) derived for a temperature-dependent gap, while the underdoped data ($\delta>0.15$) fit expression (4) for a $T$-independent gap. The fact that the underdoped sample data scale onto one universal curve in Fig. 2(b), while the near optimally doped data scale onto the curve in Fig. 2(c), is a consequence of the scaling properties of Eqs. (4) and (6) and is a rather remarkable confirmation of the theoretical model by the experiment. From the fits of the underdoped sample data, we obtain gap values of $2\Delta=(5 \pm 1)k_BT^*$ for underdoped samples and $2\Delta=(9 \pm 1)k_BT_c$ for the near optimally doped samples, the latter in good agreement with other optical experiments.$^{1,16}$

Further confirmation of the model comes from the predicted linear intensity dependence in Eqs. (4) and (6). In Fig. 3 we plot the $T$ dependence of $|\Delta T/T|$ for a near optimally doped sample ($T_c=89$ K) for three different pump intensities. The data are seen to scale linearly with intensity as shown by the inset where $\xi_f$ is changed over one order of magnitude. (Unfortunately, measurements over a larger range of intensities were not possible because of steady-state laser heating.)

B. Anisotropic gap with nodes

If the gap is anisotropic and contains nodes on the Fermi surface—such as for $d$-wave or strongly anisotropic $s$-wave pairing—there is no clear gap in the spectrum. Nevertheless, the quasiparticle DOS still has a strong energy dependence and a separation of low- and high-energy quasiparticles still
exists, albeit less pronounced than in the isotropic case. For an anisotropic gap with nodes we can approximate the quasiparticle DOS as a function of energy $\epsilon$ as

$$N(\epsilon) = N(0) \left( \frac{\epsilon}{\Delta_0} \right)^{\eta} \left( \epsilon \ll \Delta_0 \right), \quad (7)$$

where $\Delta_0$ is a characteristic energy scale separating the low- and high-energy QP’s, and the exponent $\eta$ depends on the topology of the nodes on the Fermi surface. For a two-dimensional Fermi surface (with nodes) $\eta = 1$, while for a three-dimensional case $\eta = 2$.

Using Eq. (7) we can estimate the average energy accumulated by quasiparticles after each laser pulse:

$$\Delta E = 2F_N(0)(k_B T'_{\text{rel}})^{1(\eta + 2)} / \Delta_0^{\eta} = \mathcal{E}_I, \quad (8)$$

$$F = \int_0^\infty \frac{x^{\eta + 1}}{\exp(x) + 1} dx. \quad (9)$$

$F = 1.80$ for $\eta = 1$, and $F = 5.68$ for $\eta = 2$, and $T'$ and $T$ are the QP temperature and lattice temperatures, respectively. At low temperatures, the phonon contribution to the total energy is exponentially small [Eq. (8)] and can be neglected. In this case, the high- and low-energy phonons are separated by an energy scale of the order of $\Delta_0$. (Note that in general $\Delta_0$ scales with the gap, but is not equal to the amplitude of the gap.)

Solving Eq. (8) with respect to the QP temperature $T'$ we obtain

$$T' = \left[ \frac{\mathcal{E}_I \Delta_0}{2F_N(0)} + k_B T_{\text{rel}}^{1(\eta + 2)} \right]^{1/\eta + 2}. \quad (10)$$

The number of thermally excited quasiparticles is determined by the equation

$$n_T = 2G(0)k_B T_{\text{rel}}^{1/\eta + 1} / \Delta_0^{\eta}, \quad (11)$$

where $G$ is given by the Eq. (9), except that $\eta + 1$ is replaced by $\eta$. So $G = 0.82$ for $\eta = 1$ and $G = 1.80$ for $\eta = 2$. Combining the two equations (10) and (11), we derive the following equation for the number of photogenerated quasiparticles as a function of temperature:

$$n_{pe} = \frac{2G(0)k_B T_{\text{rel}}^{1/\eta + 1}}{\Delta_0^{\eta}} \left[ 1 + \frac{\mathcal{E}_I \Delta_0^{\eta}}{2F_N(0)k_B T_{\text{rel}}^{1(\eta + 2)}} \right]^{1/\eta + 2} - 1. \quad (12)$$

The expression for the photoinduced carrier density [Eq. (12)] is plotted in Fig. 4 with $\eta = 2$ (solid line) and the same values of $N(0)$ and $\mathcal{E}_I$ as before. Instead of an exponential falloff with increasing temperature, the photoexcited quasiparticle number decreases rapidly well below $T_c$ according to a power law. In the two-dimensional case with $\eta = 1$ (and the same parameters), the temperature dependence is shown by the dashed line in Fig. 4 and differs only at the lowest temperatures. Using a $T$-dependent gap (e.g., of BCS form) in Eq. (12), the curve for $n_{pe}$ is virtually indistinguishable from the case where $\Delta_0^{\eta}$ is temperature independent. The reason for this is that the effect of the $T$-dependent gap is only important as $T \to T_c$, but there $n_{pe}$ is already small.

At low temperatures we can neglect the 1 in the large parentheses and obtain

$$n_{pe} = \frac{2 \mathcal{E}_I}{k_B T_{\text{rel}}^{1/\eta + 2}}. \quad (14)$$

A feature of the $d$-wave model, which is particularly important for comparison with experiment, is the peculiar sublinear behavior of $n_{pe}$ with laser pump intensity $n_{pe}$ at low temperatures. In the high-temperature limit on the other hand we can expand the term in brackets to obtain a crossover to linear behavior, with a temperature-dependent slope:

$$n_{pe} = \frac{2 \mathcal{E}_I}{k_B T_{\text{rel}}^{1/\eta + 2}}. \quad (14)$$

It should be pointed out that in the high-temperature limit, the phonon contribution should become increasingly important and the decrease of the number of photogenerated QP will eventually become exponential, just as in the case of an isotropic gap.

The data for the temperature dependence of the induced transmission for underdoped and optimally doped YBa$_2$Cu$_3$O$_{6.9}$ are also plotted in Fig. 4, superimposed with the predicted response for the $d$-wave case. Clearly the $T$-dependence data cannot be described using a pure $d$-wave gap irrespective of dimensionality or the form of temperature dependence of $\Delta(T)$ [Eq. (12)]. The linear intensity dependence shown in Fig. 3 is consistent with this observation, and is also not consistent with a $d$-wave gap, which predicts a sublinear response. We note that although the data apparently exclude the possibility of a pure $d$-wave gap in under-
doped and near optimally doped YBCO, it does not entirely rule out a mixed symmetry gap with some $d$-wave admixture.

V. THE QUASIPARTICLE RELAXATION RATES

As discussed in Sec. III, the relaxation rate of the photoinduced QP’s is dominated by the energy transfer from high-frequency phonons with $\hbar \omega > 2\Delta$ to phonons with $\hbar \omega < 2\Delta$. To describe the relaxation of nonequilibrium quasiparticles in this case we consider the kinetic equation for phonons, taking into account phonon-phonon scattering:

$$\frac{\partial n_{\omega}}{\partial t} = I_{ph-ph}(n_{\omega}),$$

(15)

where phonon-phonon scattering integral has the form

$$I_{ph-ph}(n_{\omega}) = 2\pi \sum_{q_1,q_2} w_{q_1,q_2} \left\{ \frac{1}{2} \left[ (n_{\omega}+1) n_{\omega} n_{\omega-2} \right. \right.$$  

$$- n_{\omega}(n_{\omega}+1)(n_{\omega}+1) \delta(\omega - \omega_1 - \omega_2)$$  

$$+ \left[ (n_{\omega}+1)(n_{\omega}+1)n_{\omega_2}-n_{\omega} n_{\omega} \right]$$  

$$\left. \times (n_{\omega}+1) \delta(\omega_2 - \omega_1) \right\}.$$  

(16)

$$\sum_{q(q) < 2\Delta} \omega_{q} I_{ph-ph}(n_{\omega}) = 2\pi w^2 \int_{0}^{2\Delta} \omega \rho(\omega) d\omega \int \frac{1}{2} \left\{ \frac{1}{2} \left[ (n_{\omega}+1)n_{\omega_2} n_{\omega_2} - n_{\omega}(n_{\omega_2}+1)(n_{\omega_2}+1) \right] \rho(\omega) \rho(\omega - \omega') \right.$$  

$$+ \left[ (n_{\omega}+1)(n_{\omega_2}+1)n_{\omega_2} n_{\omega_2} - n_{\omega} n_{\omega_2} \right]$$  

$$\left. \times (n_{\omega_2}+1) \delta(\omega_2 - \omega_1) \right\} d\omega'. \right.$$  

(18)

Here $\rho(\omega) = 3\nu \omega^3/\Omega_c^3$ is the phonon density of states in the Debye approximation. We restrict ourselves to a discussion of the relatively high temperature limit where the phonon distribution function can be replaced by $k_B T/\hbar \omega$. The energy accumulated by the phonons with $\hbar \omega < 2\Delta$ is

$$E_\omega = \int_{0}^{2\Delta} n_{\omega} \rho(\omega) \hbar \omega d\omega = \frac{8 \nu k_B T^3}{(\hbar \Omega_c)^3}.$$  

(19)

In the integral Eq. (18) the first term is equal to 0 because it has only phonon distribution functions with $\hbar \omega < 2\Delta$. The first nonzero contribution describes the decay of the phonon with $\hbar \omega > 2\Delta$ to two phonons with $\hbar \omega < 2\Delta$:

$$I_1 = \frac{13}{12} \pi w^2 \frac{3\nu}{(\hbar \Omega_c)^3} k_B^2 T^3 (T' - T)(2\Delta)^7.$$  

(20)

The second contribution describes the inelastic scattering of a high-frequency phonon with creation of one low-frequency phonon with $\hbar \omega < 2\Delta$:

$$w_{q_1,q_2}$$ is the anharmonic coupling constant and $n_{\omega}$ is the phonon distribution function. (Conservation of the phonon momentum is not relevant because of umklapp scattering.) We neglect the electron-phonon scattering integral because at normal temperatures the relative contribution of quasiparticles to the relaxation of phonons is small due to the relatively small number of quasiparticles compared to the phonons $N(0)\Omega_c < \nu$. Electron-phonon collisions can play an important role only at temperatures $T' \ll T$, but since—as shown in the previous section—$n_{pe}$ is nearly constant at low temperature, $T'$ cannot be small. The distribution function Eq. (1) reduces to 0 the parts of the collision integral Eq. (16) that describe the scattering of high- and low-frequency phonons separately. Only the part of the collision integral that does not conserve the number of phonons with $\hbar \omega < 2\Delta$ differs from zero.

To estimate the relaxation time, we multiply Eq. (15) by $\omega_q$ and sum over $q$, satisfying the condition $0 < \omega_q < 2\Delta(T)$:

$$\frac{\partial E_q}{\partial t} = \sum_{q(q) < 2\Delta} \hbar \omega_q I_{ph-ph}(n_{\omega}).$$

(17)

If we suppose that the coupling constant is momentum independent $w_{q_1,q_2} = w$, then

$$I_2 = \frac{8}{3} \pi w^2 \left( \frac{3\nu}{(\hbar \Omega_c)^3} \right)^3 k_B^2 T^3 (T' - T)(2\Delta)^7.$$  

(21)

Equation (21) shows that the inelastic scattering of high-frequency phonons is dominant in the energy relaxation of the energy if $\Delta \approx \hbar \Omega_c$, and we can neglect $I_1$.

Taking into account Eqs. (17) and (19)–(21) we obtain expressions describing the relaxation of the equilibrated QP-phonon temperature:

$$\frac{\partial T}{\partial t} = \frac{1}{\tau_{ph}} (T' - T),$$

(22)

$$\frac{1}{\tau_{ph}} = \frac{9 \pi w^2 k_B T^3 (T' - T)}{(\hbar \Omega_c)^3}.$$  

(23)

Note that Eq. (22) is rather similar to that derived by Allen\textsuperscript{10} for the temperature relaxation in the electron-phonon system in the normal metals, except that Eq. (22) describes the phonon energy relaxation modified by the gap in the quasiparticle spectrum.
The phonon-phonon relaxation time [Eq. (23)] can be expressed in terms of an experimental parameter, namely, the Raman phonon linewidth $\Gamma_{\omega}$. Using Fermi’s “golden rule,” we can calculate $\Gamma_{\omega}$ for $k_B T \ll \hbar \omega$:

$$\Gamma_{\omega} = 2 \pi \omega^2 \sum_{q,v,v'} (n_{q,v} + 1)(n_{q,-v} + 1) \times \delta(\omega_{q,v} + \omega_{-q,v} - \omega) = \frac{3 \pi \omega^2 \nu^2 \omega^2}{4 \hbar \Omega_c^2}.$$ (24)

The phonon relaxation rate can thus be expressed in terms of $\Gamma_{\omega}$ in the following form:

$$\frac{1}{\tau_{ph}} = \frac{12 \Gamma_{\omega} k_B T' \Delta(T)}{\hbar \omega^2}.$$ (25)

For a temperature-dependent gap $\Delta$, the relaxation time is expected to show a divergence $\tau_{ph} \propto 1/\Delta(T)$ as is indeed observed in optimally doped cuprates. A similar divergence of the relaxation time has been calculated previously by Schmidt and Schön and Tinkham and Clark, albeit for somewhat differently created nonequilibrium situations.

The typical relaxation time scale $\tau_{ph}$ given by Eq. (25) is very close to the experimentally observed values. From the data on the Raman linewidth of the $A_{1g}^\ast$-symmetry apical O(4) phonon mode in YBCO, which has been shown to be particularly anharmonic, $\Gamma_{\omega} \approx 13$ cm$^{-1}$ and $\omega = 400$ cm$^{-1}$. At $T' \approx T = T_c/2$, and using $\Delta_{T_c/2} \approx 200$ cm$^{-1}$ we obtain $\tau_{ph} = 0.8$ ps.

At low temperatures the quasiparticle temperature $T'$ is much higher than the lattice temperature $T$ and the formula is expected to fail. However, from the experiments (Fig. 2) we see from the temperature dependence of $\Delta(T)$ that the number of photogenerated quasiparticles is nearly constant at low $T$. $T'$ can therefore be estimated from the equation

$$n_{T'} - n_T = \frac{\epsilon_f}{\Delta(0)}.$$ (26)

Taking into account that $n_{T'} \approx 2 N(0) \Delta(0) \exp\left[-\Delta(T)/k_B T\right]$ we obtain

$$k_B T' = \Delta(T)/\ln(1/[\epsilon_f/2N(0)\Delta(0)^2 + \exp\left[-\Delta(T)/k_B T\right])].$$ (27)

At low $T$, the nonequilibrium temperature $T'$ is $\Delta(T)/\ln(2N(0)\Delta(0)^2/\epsilon_f) \approx T_c/2$, while in the high-temperature limit, the exponent in the logarithm becomes large and $T' \approx T$. Combining Eq. (25) and Eq. (27) we obtain an expression for the QP relaxation time as a function of lattice temperature $T$ and photoexcitation energy $\epsilon_f$ that is valid for all temperatures $0 < T < T_c$:

$$\frac{1}{\tau_{ph}} = \frac{12 \Gamma_{\omega} \Delta(T)^2}{\hbar \omega^2 \ln(1/[\epsilon_f/2N(0)\Delta(0)^2 + \exp\left[-\Delta(T)/k_B T\right]])}.$$ (28)

To enable comparison of this formula with experiments, we again use Raman data on high-frequency optical phonon linewidths, a value of gap frequency of 200 cm$^{-1}$ ($2\Delta \approx 9 k_B T_c$) from the fits in Fig. 2(c), the same values of $N(0) = 2.2 \times 10^{-1}$ cm$^{-1}$ spin$^{-1}$ as in Sec. III, and a BCS function for $\Delta(T)$. $\epsilon_f$ was again calculated using an incident laser energy of 0.2 nJ incident on a 100-nm-thick film with a spot size of $\sim 100$ μm diameter. We obtain a temperature dependence of the relaxation time $\tau_{ph}$ as shown in Fig. 5.

A comparison of the data with the theory for optimally doped YBa$_2$Cu$_3$O$_{7-\delta}$ samples shows good agreement with the theory with $\tau_{ph} \propto 1/T$ at low $T_c$. Some experimental data in the literature show an upturn in relaxation time at low temperatures, which is also weakly present in the data in Fig. 5. Although Eq. (28) is derived for temperatures close to $T_c$, an upturn at low temperature cannot be reproduced by this formula if we reduce the energy per pulse $\epsilon_f$.

To end this section we briefly make a quantitative comparison of the relaxation rates for a gapped and gapless material. Comparing the relaxation time for the case of a gapped material with relaxation time in a normal metal described by the formula of Allen we obtain

$$\frac{\tau_{ph}}{\tau_{c,ph}} \sim \frac{\lambda \hbar^3 \omega^4}{4 \pi (k_B T)^3 \Delta \Gamma_{\omega}}.$$ (29)

Inserting experimental values for $\omega$ and $\Gamma_{\omega}$ we find the anharmonic phonon decay time in a superconductor to be approximately two orders of magnitude slower than electron-phonon relaxation in a gapless material as $\tau_{ph}/\tau_{c,ph} \approx 0.6-200$ for $T \approx T_c$ as expected.

The calculation was performed assuming that the rate limiting step for QP relaxation is anharmonic decay of high-energy phonons, while direct electron phonon relaxation was
assumed to be small. This is now justified quantitatively by a calculation of the direct electron-phonon relaxation rate. The contribution of phonon-electron scattering to the relaxation of phonon system can be estimated by deriving the corresponding relaxation rate $\tau^{-1}$ using the usual electron-phonon collision integral (see Appendix):

$$\frac{1}{\tau_1} = \frac{\pi N(0) \lambda \Delta(T) \Omega_c}{2 \nu}.$$  \hspace{1cm} (30)

We see that the electron-phonon relaxation rate, when compared to the phonon relaxation rate, is reduced by the factor $N(0) \hbar \Omega_c / \nu \approx 1$:

$$\frac{\tau_{ph}}{\tau_1} = \frac{\pi \hbar^2 N(0) \lambda \omega^2 \Omega_c}{24 \nu^4 \hbar^3 k_B T} < 1$$  \hspace{1cm} (31)

and can therefore be neglected. However if the number of phonon modes involved in the relaxation is significantly smaller, the ratio $\tau_{ph} / \tau_1$ may approach unity. In this case the electron-phonon collisions can also contribute to the phonon relaxation. However, the temperature dependence of the relaxation rate $1/\tau_1$ is very similar to the anharmonic relaxation $\tau_{ph}$, both being proportional to $\Delta(T)$ and so the two contributions to the relaxation may be difficult to separate experimentally. The data shown in Fig. 5 are fit to $\tau_{ph}$ without any fitting parameters, so it appears to be reasonable to assume that anharmonic relaxation described by Eqs. (25) and (28) is dominant in YBa$_2$Cu$_3$O$_{7-\delta}$ near optimum doping.

VI. DISCUSSION

Near optimum doping in YBa$_2$Cu$_3$O$_{7-\delta}$ ($\delta<0.1$) we find that the theoretical model gives a good quantitative fit to the temperature dependence of the photoinduced transmission [Fig. 2(c)], provided we use a temperature-dependent gap [Eq. (6)]. The relatively square shape of the temperature dependence of $|\Delta(T)|$, the weak maximum near $T/T_c=0.7$, and the rapid drop in the signal amplitude above this temperature are a consequence of the particular temperature dependence of the gap with the property that $\Delta(T) \rightarrow 0$ as $T \rightarrow T_c$. In underdoped YBCO on the other hand [Fig. 2(b)], the temperature dependence is much weaker and can only be reproduced by the calculation using a temperature-independent gap [Eq. (4)]. It is not possible to reproduce the temperature dependence of the optimally doped data using a temperature-independent gap, and vice versa, it is not possible to describe the underdoped data with a $T$-dependent BCS-like gap.  

A similar conclusion regarding the evolution of the gap with doping is reached on the basis of the comparison of the calculated temperature dependence of the relaxation time $\tau$ with the data. The divergence at $T_u$ shown in Fig. 5 for samples near optimum doping together with the temperature dependence of $|\Delta(T)|$ lead to the inescapable conclusion that there is a gap in YBa$_2$Cu$_3$O$_{7-\delta}$ with ($\delta<0.1$) that closes rapidly at $T_c$. On the other hand, the notable absence of this divergence of $\tau$ for underdoped YBa$_2$Cu$_3$O$_{7-\delta}$ ($\delta>0.15$) (Ref. 5) is consistent with the existence of a $T$-independent gap deduced from the temperature dependence of $|\Delta(T)|$.

Plotting the temperature $T^*$ and $T_c$ as a function of $\delta$ in Fig. 6, we find that $T^*$ drops with increasing doping in a characteristic fashion, following the so-called “pseudogap” behavior reported by other experimental techniques. 25-27 Near optimum doping, the “pseudogap” becomes observable close to $T_u$. Such a situation occurs in BCS superconductors where gap formation is a collective effect and Cooper pairs form simultaneously with the formation of a phase coherent collective state at $T_c$. However, from Fig. 2(c) and Fig. 3 there is some evidence of remaining QP excitations above $T_c$ even near $\delta=0.1$. The $T$-independent “pseudogap” thus appears to be still present near optimum doping, and the BCS case is not quite realized.

The underdoped state is distinctly different, with a $T$-independent normal-state pseudogap appearing at $T_u \approx T_c$. The changes in the photoinduced transmission $|\Delta(T)|$ at $T^*$ in this case are simply a result of an increased population of pairs with decreasing temperature. Since the observed changes in $|\Delta(T)|$ are associated only with pairing and not phase coherence (which occurs at $T_c$), we see no change in $|\Delta(T)|$ at $T_c$ in agreement with predictions of preformed pairing models of the underdoped state. 28,29 The pseudogap in this case signifies the pair-binding energy, and its value is determined by the microscopic pairing mechanism. It is to first approximation temperature independent and decreases with an inverse law with increasing carrier concentration, which is consistent with increased semiclassical (Debye-Hückel) screening between charge carriers. 28

Since the temperature dependence of $|\Delta(T)|$ is actually exponential at high temperatures [Eq. (4)], it is more appropriate to discuss the doping dependence of the magnitude of the energy gap $\Delta$ rather than of $T^*$. This avoids the somewhat arbitrary criterion for determining $T^*$ of an asymptotic function. Such a plot of $\Delta$ versus doping $\delta$ is shown in Fig. 7. As predicted on the basis of screening arguments above, $\Delta$ appears to follow an inverse law $\Delta \propto 1/\delta$, where $\delta=0.6-\delta$ is proportional to the carrier concentration.

The doping dependence of $\Delta$ can be independently confirmed from the same data set by plotting the low-temperature value of $|\Delta(T)|$ as a function of $\delta$. As can be
We conclude by noting that the comparison of the theoretically predicted temperature dependence of the photoinduced absorption signal amplitude and relaxation time $\tau$ with the experimental results on underdoped and optimally doped $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}$ gives good quantitative agreement. The evolution of the gap from a temperature-independent $\Delta$ to a temperature-dependent collective gap $\Delta(T)$ is a particularly striking feature of the data as is the apparent inverse dependence of the gap magnitude with doping. Although the model calculation presented in this paper was performed with the superconducting cuprates in mind, it is quite general and can, for example, also be applied to a case of photoexcitation experiments on charge density-wave (CDW) systems or narrow-gap semiconductors. It could also be extended for other nonequilibrium situations as might occur in nonequilibrium superconducting high-$T_c$ devices for example.

**ACKNOWLEDGMENTS**

We would like to acknowledge K. A. Müller, R. Hackl, and A. S. Alexandrov for valuable comments and discussions. Furthermore, we would like to acknowledge the support from ULTRAFAST Network. One of us (V.V.K.) acknowledges support of this work by RFBR Grant No. 97-02-16705 and by the Ministry of Science and Technology of Slovenia.

**APPENDIX**

To estimate the electron-phonon relaxation rate we take into account the electron-phonon collision integral:13

$$I_{\text{ph}}(n_a) = -4\pi \sum_k |M_{kk'}|^2 f_k (1-f_{k'}) n_q$$

$$- f_{k'} (1-f_k) (n_q+1) \delta(\epsilon_k - \epsilon_{k'} + \omega_q).$$

$M_{kk'}$ is electron-phonon coupling constant and $n_a$, $f_k$ are phonon and electron distribution functions.

Note that we neglect coherence factors in the electron-phonon collision integral. This is a reasonable approximation for the BCS case if the characteristic energy of quasiparticles is large in comparison with the gap $T>\Delta$. For underdoped case also, the normal-state gap is temperature independent and hence coherence factors are equal to 0. It is easy to show that the collision integrals satisfy the conservation energy law:10

$$2 \sum_k \epsilon_k \left( \frac{df_k}{dt} \right) + \sum_q \omega_q \left( \frac{dn_q}{dt} \right) = 0.$$
make the Debye approximation for the electron-phonon spectral function $\alpha^2 F(\Omega) = \lambda \Omega^2 / \Omega_c^2$.

\[
\sum_{q, \omega_q < 2\Delta} \omega_q e^{-\beta \omega_q} \langle n_\omega \rangle = -2\pi N(0) \int_0^{2\Delta} \Omega \alpha^2 F(\Omega) d\Omega \\
\times \int_\Delta^\infty \{ [f(\epsilon) - f(\epsilon + \Omega)] n_\Omega \\
- f(\epsilon + \Omega) [1 - f(\epsilon)] \} d\epsilon. \quad (A1)
\]

The integral Eq. (A1) can be easily evaluated:

\[
I_1 = \frac{4\pi k_B N(0) \lambda \Delta^4}{\hbar^2 \Omega_c^2} (T' - T). \quad (A2)
\]

Formula (A2) leads to Eq. (30) for electron-phonon relaxation rate.

---

15. Solving Eq. (4) numerically without the approximate formula for \( n_T \), it can be shown that formula (6) is accurate within <10% over the whole temperature interval.
22. The divergence in \( \tau \) appears approximately 5–8 K below \( T_c \). Possibly this is due to a nonuniform temperature profile within illuminated area.
24. Here the term temperature-independent gap means that the gap does not vanish at \( T_c \), but persists above \( T_c \). It does not exclude the possibility of a weakly temperature dependent gap.
